Summary

Symbolic thermoeconomics is a methodology for the analysis of the productive structure, and the natural resources consumption process in energy systems. It appears as a technique, based on the Exergy Cost Theory, to obtain general equations, which relate the overall efficiency of an energy system and other thermoeconomic variables as fuel, product, exergy cost, with the efficiency of each component which forms it. By mean of the equations obtained, it is possible to analyze the influence of the individual consumption of each component on the total amount of external resources required to obtain a product. Therefore, the productive structure and the cost formation process of the products are explained.

1. Introduction

The cost accounting methodologies, as Exergy Cost Theory, propose methods to determine the amount of resources required for obtaining a product. They are based on cost assessment rules, which attribute to the useful product the resource cost of each
component, and distribute its costs proportionally to its exergies. They are mainly numerical techniques that calculate the cost values in an accurate way, by solving sets of linear equations, but they cannot identify the causes of the cost formation process.

Suppose the thermal system shown in Figure 1. In this article it is explained the procedure for obtaining the global efficiency of the system as a function of the efficiencies, $\zeta_i$, of its components is:

$$
\zeta_T = \frac{\zeta_1 (y_2 (1 - y_3) \zeta_2 + (1 - y_3) \zeta_3)}{1 - y_2 y_3 \zeta_2 \zeta_3}
$$

where terms $y_i$ represents the bifurcation ratios.

This poses some initial questions: Could we obtain such a formula in a general way? What conditions must fulfill our method to assess it? If such a formula exists, questions of the type, what happens if?, could be simplified. Thus we could compute, for example, how a variation in the efficiency of a component modify the efficiency of the whole plant. With general formulae we can get general solutions to general problems. The proposed analysis provides a set of valuable tools for the cost accounting, diagnosis, optimization and synthesis of energy systems.

Symbolic computation packages, like Mathematica or MatLab, could be used to solve a wide variety of technical computing problems, such as to obtain both analytical and numerical solutions of linear systems of equations. If we bring together Exergy Cost Theory and Symbolic Computation then it will be possible to find out a general way to obtain formulae like that shown above. This was the reason to call this methodology Symbolic Thermoeconomics. Some of its applications are presented in the bibliography listed at the end of this article.

Figure 1. Gas turbine cycle diagram.
In order to follow the arguments of the proposed methodology, we use a simple example of a power plant, whose block diagram, design and operational exergy flow values are shown in Figure 1. The plant is made up of a cogeneration gas turbine cycle, and uses the turbine outlet gases as thermal energy in a heat recovery steam generator, that produces steam (flow #7) together with the electric energy produced in the turbogenerator (flow #6).

2. The Fuel-Product Model

The first stage to identify the cost process formation consists of building, from the physical structure of the plant, a productive scheme which shows where the product of each component is used and the origin of the resources of each component.

The problem of the productive structure identification is closely related to Leontief's input-output economic analysis. It consists of a qualitative and quantitative analysis of the relations that link the flows of goods and services between the components of an economic unit, in order to study its structural characteristics.

An equivalent model could be applied to thermal systems. It can be represented by a fuel/product diagram, such as shown in Figure 2 and Table 1, for the plant of the example. It is also called in other thermoeconomic methodologies Functional Diagram.

</table>

Table 1. Fuel/product table.
Note that, not all products of components #1 and #2 are used as resources in components #3, #4 or final product, the flow #8 is a residue generated in components #1 and #2.

\[ r_1 = \frac{E_3 - E_2}{E_3} \quad r_2 = \frac{E_2}{E_3} \quad r_1 + r_2 = 1 \]

In accordance with this model the production of one component is used as fuel of another component or as a part of the total production of the plant:

\[ P_i = E_{i0} + \sum_{j=1}^{n} E_{ij} \quad i = 0, 1, \ldots, n \quad (1) \]

where \( E_{ij} \) is the production portion of the \( i \)-th component that fuels the \( j \)-th component.

In the above expression, we consider the component 0, as the system environment, then \( E_{0i} \) represents the production portion of the component \( i \) which leads to the final product, coming from the environment to the component \( i \).

On the other hand, the resources entering each component, could be expressed as:

\[ F_i = E_{0i} + \sum_{j=1}^{n} E_{ji} \quad i = 0, 1, \ldots, n \quad (2) \]

where \( E_{0i} \) represents the external resources entering to the plant, which go into the \( i \)-th component.

Therefore, the total fuel and product of the system could be expressed as:

\[ F_T = P_0 = \sum_{j=1}^{n} E_{0j} \quad P_T = F_0 = \sum_{j=1}^{n} E_{j0} \quad (3) \]
